## **Corneal collagen cross-linking as treatment for infectious and non-infectious corneal melting in cats and dogs: results of a prospective, non-randomized, controlled trial**

Pot, Simon A ; Gallhöfer, N S ; Matheis, F L ; Voelter-Ratson, K ; Hafezi, F ; Spiess, B M

**Abstract:** **OBJECTIVE.** UV-A/Riboflavin crosslinking of corneal collagen fibers (CXL) is a highly promising therapy for corneal melting in humans. A prospective interventional, non-randomized, controlled study was conducted to compare the stabilizing effect of CXL treatment on melting keratitis in dogs and cats and the complication rate of CXL to those of standardized intensive medical treatment. **PROCEDURES.** Forty-nine eyes with melting keratitis were included in the study between October 2009 and October 2012. All eyes were treated according to the same medical treatment protocol. Nineteen eyes were CXL-treated and 30 eyes were not. Follow-up included slit-lamp examination, fluorescein staining, ulcer size measurement, stromal stability evaluation, photographic documentation and documentation of complications. **RESULTS.** Five of 19 eyes in the CXL group and 9/30 eyes in the control group required rescue stabilization due to continued melting. Seven of the 9 control group corneas stabilized after rescue CXL treatment. At initial presentation, the ulcers in the canine CXL group were significantly deeper and larger than in the control group. Ulcer deepening during follow-up was more pronounced in the canine control group than in the canine CXL group. CXL treatment related complications were not observed. **CONCLUSIONS.** Based on the similar failure rates in the control and CXL treatment groups despite the poorer initial situation in the CXL group, the tendency for the ulcers in the control group to deepen and the stabilization of all corneas receiving CXL rescue treatment, we believe that CXL has its place as an adjunctive therapy for melting keratitis in veterinary ophthalmology.

28 **Abstract**

29 **OBJECTIVE.** UV-A/Riboflavin crosslinking of corneal collagen fibers (CXL) is a highly  
30 promising therapy for corneal melting in humans. A prospective interventional, non-  
31 randomized, controlled study was conducted to compare the stabilizing effect of CXL  
32 treatment on melting keratitis in dogs and cats and the complication rate of CXL to those of  
33 standardized intensive medical treatment.

34 **PROCEDURES.** Forty-nine eyes with melting keratitis were included in the study between  
35 October 2009 and October 2012. All eyes were treated according to the same medical  
36 treatment protocol. Nineteen eyes were CXL-treated and 30 eyes were not. Follow-up  
37 included slit-lamp examination, fluorescein staining, ulcer size measurement, stromal stability  
38 evaluation, photographic documentation and documentation of complications.

39 **RESULTS.** Five of 19 eyes in the CXL group and 9/30 eyes in the control group required  
40 rescue stabilization due to continued melting. Seven of the 9 control group corneas stabilized  
41 after rescue CXL treatment. At initial presentation, the ulcers in the canine CXL group were  
42 significantly deeper and larger than in the control group. Ulcer deepening during follow-up  
43 was more pronounced in the canine control group than in the canine CXL group. CXL  
44 treatment related complications were not observed.

45 **CONCLUSIONS.** Based on the similar failure rates in the control and CXL treatment groups  
46 despite the poorer initial situation in the CXL group, the tendency for the ulcers in the control  
47 group to deepen and the stabilization of all corneas receiving CXL rescue treatment, we  
48 believe that CXL has its place as an adjunctive therapy for melting keratitis in veterinary  
49 ophthalmology.

50 **Key words:** cornea, melting keratitis, dog, cat, CXL, medical therapy

51

## 53 **Introduction**

54 Melting keratitis or keratomalacia is a serious condition which occurs with relative frequency  
55 in veterinary ophthalmology, especially in predisposed breeds.(1-4) Melting keratitis is  
56 caused by the release of endogenous and exogenous collagenolytic enzymes and an imbalance  
57 between these proteolytic enzymes and the proteinase inhibitors present in the cornea and  
58 precorneal tear film.(5, 6) Such a release of collagenases can be caused by primary diseases of  
59 the ocular surface that weaken the cornea's anatomic barriers and physiologic defenses (like  
60 low corneal sensation, quantitative and qualitative tear film deficiencies, exposure keratitis,  
61 trauma, eyelid abnormalities etc.), topical medications, systemic immune mediated diseases  
62 and secondary bacterial or fungal corneal infections.(7-10)

63 If uncontrolled, melting keratitis can lead to complete structural disintegration of the cornea,  
64 corneal perforation and eventual loss of the eye.(3, 4) Aggressive treatment with topical  
65 antimicrobials to battle a potential infection and ~~with~~ anticollagenases to directly counter  
66 collagenolysis ~~is~~ are therefore indicated to stop progression of the melting process.(5)

67 Surgical stabilization of the cornea is indicated when significant progression of the melting  
68 process despite medical therapy is observed or when the integrity of the globe is significantly  
69 compromised at initial presentation.(3) Conjunctival grafts are typically used since they  
70 provide tectonic, antimicrobial and anticollagenase support for a melting ulcer. However, the  
71 use of conjunctival grafts exacerbates the corneal opacity which develops as a result of  
72 corneal stromal ulcer healing. Depending on the initial lesion size, depth and localization, the  
73 residual visual impairment can be more or less severe.(3, 11, 12) Another major problem is  
74 the potential rapid progression of melting keratitis, which makes timely control over the  
75 disease process difficult, both with medical and conventional surgical intervention.

76 Natural covalent cross-links between the corneal collagen fibers improve the biomechanical  
77 stability of the cornea. Crosslinking of corneal collagen (CXL) uses riboflavin (Vitamin B2)

78 which acts as a photosensitizer when exposed to UV-A light with a wavelength at the  
79 riboflavin absorption peak of 370nm. This results in a photopolymerization process powered  
80 by free oxygen radicals introducing additional cross-links within and between collagen fibers  
81 in the corneal stroma up to a depth of 300 $\mu$ m.(13) The result is an increase in the  
82 biomechanical and biochemical stability of the cornea and reactive oxygen species (ROS)-  
83 induced damage to cells and microorganisms in the irradiated area.(14-18) In a riboflavin-  
84 saturated cornea of  $\geq 400\mu$ m thick, the UV-A irradiance generated at the level of the  
85 endothelium with the standard CXL procedure is less than half the endothelial damage  
86 threshold. All structures behind a 400 $\mu$ m thick corneal stroma, including the corneal  
87 endothelium, iris, lens epithelium and retina are exposed to a residual UV radiation exposure  
88 that is regarded as safe for these structures.(13)

89 Several groups have demonstrated the antimicrobial effect of CXL against a host of bacterial  
90 isolates in vitro.(19-21)

91 CXL was developed to increase the stability and reduce the biodegradation of the corneal  
92 collagen matrix in primary and secondary corneal ectatic diseases, most notably  
93 keratoconus.(22) However, the properties of CXL-induced increased corneal rigidity,  
94 decreased susceptibility to collagenase enzymes and ROS-induced toxicity to microorganisms  
95 make CXL an attractive adjunctive therapy for the treatment of melting keratitis.

96 During the last five years several groups have published studies in humans where CXL was  
97 used as an adjuvant treatment in cases where medical therapy had failed to control infectious  
98 melting keratitis. In all single cases and small case studies published, CXL led to an arrest of  
99 progression of infectious melting.(23-27) In two larger case series with 16 and 40 enrolled  
100 patients the reported success rates were 100 and 85%, respectively.(28, 29) In one of these  
101 two case series CXL was successfully used as sole treatment, without the use of antibiotics, to

102 stabilize corneas with confirmed (13 of 16 cases) and presumed (3 of 16 cases) bacterial  
103 keratitis.(28)

104 The use of CXL as an adjunctive therapy for the treatment of melting keratitis may become its  
105 major indication in veterinary medicine. We have recently published a pilot study describing  
106 the successful use of CXL to treat melting keratitis in three dogs and three cats. Superficial  
107 corneal pigmentation, sequestrum formation and bullous keratopathy were observed during  
108 follow-up. It was unclear whether these pathologies were preexisting conditions or  
109 complications of the CXL treatment and/or the initial melting keratitis.(30) Hellander-Edman  
110 et al. have described the successful stabilization via CXL of eight out of nine equine corneas  
111 with melting keratitis.(31)

112 Antimicrobial drug resistance of pathogens seems to be an increasing problem in veterinary  
113 ophthalmology.(32, 33) The treatment of certain drug resistant microorganisms may be  
114 facilitated by the direct antimicrobial effect of CXL.(19)

115 As far as the authors know, no controlled clinical studies attempting to compare the efficacy  
116 of CXL to that of medical treatment for melting keratitis have been undertaken.

117 Therefore, the objectives of this study were to (i) assess the effectivity of CXL treatment in  
118 stabilizing the cornea of dogs and cats with melting keratitis and (ii) to compare the  
119 effectivity and complication rate of CXL to those of an intensive standard medical treatment  
120 protocol.

121

122

## 123 **Materials and methods**

### 124 **Trial design**

125 | [A p](#)Prospective interventional, non-randomized, controlled study [was](#) designed to assess  
126 whether CXL treatment of eyes suffering from melting keratitis can decrease the incidence of  
127 surgical salvage procedures necessary to stabilize the cornea and of surgical globe removal.  
128 The purpose of the study was to test the null-hypothesis stating that no difference in outcome  
129 exists between the patient group undergoing CXL + medical treatment compared to the  
130 control group of patients receiving medical therapy alone.

### 131 **Animals**

132 Forty-nine eyes (46 animals) with corneal melting were included in this interventional  
133 prospective study between October 2009 and October 2012. The entry criteria for inclusion  
134 into the study were: (i) species (dog or cat), (ii) clinical diagnosis of keratomalacia/melting  
135 keratitis (see pretreatment examination), (iii) complete ophthalmic examination by a board  
136 certified ophthalmologist (BS, SP) or an A/ECVO ophthalmology resident (NG, FM, KV) at  
137 initial presentation and all subsequent rechecks, (iv) willingness and ability of the owner to  
138 comply with the intensive topical treatment schedule and to return for follow up  
139 examinations. The presence of a corneal perforation or descemetocele or the complete  
140 absence of any normal appearing corneal stroma in the ulcer site led to exclusion from the  
141 study.

### 142 **Pretreatment examination**

143 Pretreatment analysis included slit-lamp examination, fluorescein staining, measurement of  
144 ulcer size using calipers, photography, cytology and corneal culture and sensitivity testing.  
145 Cytology samples were collected from all animals apart from two dogs in the control group,  
146 and two dogs and two cats in the CXL-treated group. Culture and sensitivity samples were  
147 collected from all cats and all dogs, apart from one dog in the CXL-treated group. The  
148 diagnosis of corneal melting was based on a subjective evaluation of stromal stability/melting  
149 activity, including the presence of cellular infiltrates, the perceived stability of the stroma, the

150 presence of changes in corneal contour and ulcer depth and the presence of malacic corneal  
151 material in the ulcer area.

## 152 **Experimental groups:**

153 All patients were treated according to the same standard medical treatment protocol, including  
154 the use of topical antibiotics, topical and systemic collagenase inhibitors and, if needed,  
155 topical atropine 1% and systemic meloxicam and buprenorphine. Table 1 summarizes the  
156 medical treatment protocol. The patients were divided into two groups depending on whether  
157 the cornea was CXL-treated or not. Patients in the control group were client owned animals  
158 meeting the entry criteria that were treated with medical treatment alone. Thirty eyes (27  
159 animals, 23 dogs and 4 cats) were enrolled in the control group. Patients in the CXL group  
160 were client owned animals meeting the entry criteria that were treated with medical treatment  
161 **and** CXL. Nineteen eyes (19 animals, 12 dogs and 7 cats) were enrolled in the CXL group.  
162 Discontinuation of medical treatment was judged unethical in light of the unknown efficacy  
163 of CXL treatment in dogs and cats. Allocation to treatment groups was not performed  
164 randomly and depended on owner and clinician preference. Table 2 demonstrates the  
165 composition of the study groups.

## 166 **The CXL procedure**

167 CXL was performed as previously described.(30) Briefly, all procedures were performed  
168 under general anesthesia with the eye anesthetized topically and positioned in a horizontal  
169 plane (Fig. 1). Isoosmolar 0.1% riboflavin drops (freshly mixed 0.5% aqueous riboflavin  
170 (Vitamin B2; Streuli, Uznach, Switzerland) and sterile 20% dextran T-500 solutions) were  
171 administered to the cornea every 3 minutes for 30 minutes. The corneas were then irradiated  
172 for 30 minutes with a 365 nm wavelength ultraviolet A light (irradiance: 3 mW/cm<sup>2</sup>, UV-X;  
173 Peschke Meditrade, Cham, Switzerland) focused on the corneal surface, while taking care to  
174 avoid the corneal limbus.(34, 35) Riboflavin solution was applied to the cornea every 3

175 minutes during the irradiation period. CXL was performed in the presence of a certain risk of  
176 UV-induced cytotoxicity to the endothelium in corneas demonstrating significant loss of  
177 corneal stroma.

#### 178 **Posttreatment follow-up**

179 The median available follow-up was 2 (range 0.1 to 12) months and 3 (range 0.25 to 22.5)  
180 months in the control and CXL groups, respectively. Follow up included slit-lamp  
181 examination, fluorescein staining, ulcer size measurements with calipers, photographic  
182 documentation and documentation of complications during all reexaminations.  
183 Posttreatment examinations were performed during initial hospitalization, at days 7, 14 and  
184 28 after initiation of treatment and at various timepoints during the long-term follow-up. The  
185 primary endpoint variable to be measured was the occurrence of (or need for) surgical  
186 stabilization or removal of the eye, which was interpreted as treatment failure. Surgical  
187 intervention was recommended in cases where a significant portion of the residual corneal  
188 stromal thickness was lost due to progressive corneal melting during follow up. Surgical  
189 intervention was typically recommended if an additional amount of stroma greater than 20%  
190 of the normal thickness of the cornea was lost during follow up. For eyes in the control group,  
191 CXL was offered as 'surgical' stabilization option. The time interval between treatment  
192 initiation and the stabilization of the corneal stroma (as determined by the lack of signs of  
193 melting, see pretreatment examination), the time interval between treatment initiation and  
194 closure of the corneal defect (defect fluorescein negative) and the registration and  
195 documentation of complications were secondary endpoint variables.

#### 196 **Statistical evaluation**

197 Treatment failure/success, gender and laterality were evaluated using Fisher's exact test for  
198 contingency tables. The data for dogs and cats were evaluated separately. Differences

199 between control and CXL groups regarding age, ulcer depth, ulcer size, interval treatment  
200 start to stroma stabilization, interval treatment start to defect closure, stromal thinning at last  
201 visit and length of follow up were evaluated using the Wilcoxon rank sum (Mann-Whitney U)  
202 test for unpaired non-parametric data. Differences within groups in ulcer depth at  
203 presentation, ulcer depth prior to CXL and maximal ulcer depth observed during the study  
204 period were evaluated using the Wilcoxon signed rank test for paired non-parametric data.  
205 The level for statistical significance was set at  $p < 0.05$  for all comparisons. GraphPad Prism  
206 version 6.00 for Windows (GraphPad Software, La Jolla CA, USA, [www.graphpad.com](http://www.graphpad.com)) was  
207 used for all statistical analyses.

208

209

## 210 **Results**

### 211 **Treatment groups**

212 The number of patients was unequally distributed across treatment groups. Baseline  
213 characteristics were well balanced between the canine control and CXL groups with the  
214 possible exception of low tear production ( $< 15$  mm/min) measured at presentation (Table 2).  
215 Brachycephalic animals were equally distributed over and overrepresented in the canine  
216 control and CXL groups.

217 The median age of the cats enrolled in the study was 11.5 years for the control group and 10  
218 years for the CXL group. The median age of the dogs in these groups was 3.8 and 3 years,  
219 respectively. No significant age difference was found between the control and CXL groups.

220 The right eye was affected more often in cats and more male cats than female cats were  
221 enrolled in the study. All cats in the control group were brachycephalic, whereas only 2/7 cats  
222 in the CXL group were brachycephalic.

223 **Clinical features**

224 The numbers of patients with the primary end point (treatment failure/eyes treated) by group,  
225 secondary end points, culture results and complications over a median follow-up of 1.5-5  
226 months are demonstrated in Table 3.

227 Inflammatory cellular infiltrates were present in all affected corneas and slit-lamp  
228 examination showed loss of corneal stroma in all cases. Significant progression of corneal  
229 melting was observed in 9/30 eyes (30%) in the combined canine and feline control groups  
230 and 5/19 eyes (26%) in the combined CXL groups. Surgical stabilization was recommended  
231 for these eyes and this was interpreted as failure of the allocated treatment. The median time  
232 from treatment start to failure was 2 days in the control group (range 1-24 days) with only 2  
233 of 9 eyes failing treatment after one week of follow-up. Median treatment start to failure time  
234 in the CXL group was 6 days (range 1-18 days). One eye in the feline control group failed  
235 treatment, all other eyes failing treatment were canine eyes. The number of eyes that failed  
236 treatment was not significantly different when comparing CXL treated eyes to eyes that  
237 received medical treatment alone in either dogs ( $p=0.71$ ), cats ( $p=0.36$ ) or dogs and cats  
238 combined ( $p=1$ ).

239 A conjunctival pedicle flap was used to stabilize one cornea failing treatment in the control  
240 group. Conjunctival pedicle flap placement was strongly recommended for a second control  
241 group patient but declined by the owner. Seven eyes of 6 control group animals were  
242 successfully treated with CXL as rescue therapy.

243 Four of the five corneas failing treatment in the CXL group were stabilized using a  
244 conjunctival pedicle flap. A nictitating membrane flap was used in the fifth eye to protect a  
245 descemetocoele during second intention healing. All surgically treated eyes that failed initial  
246 treatment were stabilized and retained some form of vision.

247 One patient with a suspected systemic immunodeficiency was enrolled in the CXL group and  
248 failed treatment. Two out of three patients with poorly controlled diabetes mellitus which  
249 were enrolled in the control group failed treatment. One of these two patients presented in a  
250 ketoacidotic crisis with bilateral melting keratitis and the second patient was suspected of  
251 having [Cushing's](#) disease.

252 The ulcer area size was much larger in the CXL group than in the control group in both cats  
253 (not significant) and dogs ( $p=0.01$ ). The ulcer area size was much larger in the cats than in the  
254 dogs in both groups. At presentation, the ulcers of patients in the CXL group were deeper  
255 than in the control group in dogs ( $p=0.04$ ) but not in cats. The interval from treatment start to  
256 stabilization of the corneal stroma and the interval from treatment start to closure of the  
257 epithelium over the defect were longer in the CXL group compared to the control group in  
258 dogs ( $p=0.03$  and  $0.02$ , respectively) and cats (not significant). There were no significant  
259 differences in the length of follow up between groups. The maximal ulcer depth observed  
260 during follow-up was not significantly different between the control and CXL groups. A  
261 significant increase in ulcer depth was observed in both groups in dogs when comparing the  
262 ulcer depth at presentation to the maximal ulcer depth observed during follow-up. Ulcer depth  
263 increased from a median of 35% to 50% stromal loss in the control group ( $p=0.001$ ) and from  
264 50% to 55% stromal loss in the CXL group ( $p=0.03$ ). The differences were not significant in  
265 cats. Stromal thinning at the site of the previous ulcer, estimated at the last recorded visit, was  
266 more pronounced in the control group (20%) compared to the CXL group (2.5%) in dogs  
267 ( $p=0.03$ ). No difference was observed in cats.

#### 268 **Culture and cytology**

269 One of 11 cat eyes were positive on cytology, compared to 10/38 dog eyes. All cytology  
270 positive eyes also yielded positive culture results in both dogs and cats. In dogs, 18/26 (69%)  
271 cultures were positive in the control group, compared to 5/11 (45.5%) cultures in the CXL

group. One eye in the CXL group had no culture submitted. In cats, 2/4 cultures were positive in the control group, compared to 4/7 cultures in the CXL group. Twenty-five of a total of 34 bacterial isolates were cocci of the genus Staphylococcus or Streptococcus.

## **Complications**

A certain amount of fibrosis was present at the location of the initial ulcer in all eyes, regardless of the treatment group. The density of the fibrosis varied from mild fibrosis which was not obvious to the naked eye, but easily detectable with the use of a slitlamp biomicroscope at a 10x magnification, to complete opacification of the cornea. The area size affected depended on the area size of the initial ulcer. Appearance of corneal pigmentation (4 eyes) or progression of previously existing corneal pigmentation (7 eyes) was observed in 11/26 eyes (42%) in the canine control group. Eight of these eyes belonged to brachycephalic dogs, and seven to Pugs. Appearance of corneal pigmentation (1 eye) or progression of previously existing corneal pigmentation (3 eyes) was observed in 4/12 eyes (33%) in the canine CXL group. Two of these eyes belonged to brachycephalic dogs, both Pugs. Dense corneal edema with subepithelial and intrastromal bullae was observed in one dog in the control group and in one dog in the CXL group. Corneal bullae had been observed during wound healing in the cornea of the control group patient. At three weeks after treatment start the cornea was stable and fluorescein negative and focal edema, neovascularization and fibrosis were visible. Significant superficial pigmentation, fibrosis and residual microcystic edema were observed in the cornea from the patient treated with CXL at last recheck at 7.5 months after treatment start.

One out of four cats in the control group (persian) developed a sequestrum two weeks after the start of treatment and 2/7 cats in the CXL group developed a corneal sequestrum during the corneal healing process. The first cat (ESH) developed a sequestrum two weeks after CXL and this sequestrum was spontaneously extruded three weeks later. The second cat (Persian)

297 developed a faint brown staining in the superficial stroma at the ulcer site two months after  
298 CXL. This suspected sequestrum had disappeared at recheck two months later. This cat later  
299 developed a corneal erosion and similar transient brown staining in the stroma of the fellow  
300 eye.

#### 301 **Deviations and violations of protocol**

302 (i) Surgical intervention, constituting treatment failure, was recommended if a loss of more  
303 than 20% of the corneal stroma was observed in addition to the stromal loss at presentation. In  
304 some cases an exception was made to that rule. One eye demonstrating a progression from  
305 70% to 80% stromal loss failed treatment in the CXL group. Surgical intervention was  
306 recommended for this patient because of a significant increase in ulcer area size and the  
307 presence of an instable looking, heavily infiltrated ulcer bed. One eye that was counted as a  
308 treatment success in the CXL group demonstrated ulcer depth progression from 50% to 75%  
309 stromal loss before the rest of the stroma was diagnosed as being stable. Due to a massive  
310 inflammatory cell infiltration affecting the superficial stroma of the entire cornea at  
311 presentation, the examiners were not certain whether the ulcer deepening was a result of  
312 progressive melting or merely of sloughing of the cellular infiltrates.

313 Four eyes with a stromal loss progression  $\leq 20\%$  were counted as treatment failures in the  
314 control group. One eye did not demonstrate ulcer deepening, but the appearance of additional  
315 stromal ulcers despite medical therapy instead. Two eyes with an additional stromal loss of 10  
316 and 15%, respectively, demonstrated ulcer deepening and a sudden protrusion of central ulcer  
317 bed stroma within one day. One eye demonstrated an additional loss of 20% of stroma,  
318 significant inflammatory cell infiltration of the ulcer bed, the persistent presence of coccoid  
319 bacteria on repeated cytology samples and the appearance of a lipid flare.

320 (ii) Serum treatment was discontinued shortly after CXL in one cat due to patient compliance  
321 problems and concerns regarding the sterility of the dropper bottle nozzle. One dog in the

322 CXL group did not receive topical serum, nor systemic doxycycline treatment. One dog in the  
323 CXL group received topical chloramphenicol treatment in addition to the medical protocol.  
324 CXL treatment was successful in these three patients.

#### 325 **CXL rescue therapy**

326 Seven eyes of 6 animals that failed medical therapy were successfully treated with CXL as  
327 rescue therapy. Significant ulcer deepening from 30% (median) stromal loss at first  
328 presentation to 60% (median) immediately prior to CXL ( $p=0.03$ ) had been observed. These  
329 patients were censored and the follow up data presented in table 4 was not used for the study.  
330 Interestingly, ulcer depth did not significantly progress after CXL (Fig. 2 b-e) and all seven  
331 corneas were stabilized. Follow-up time and the time intervals between CXL and stabilization  
332 of the stroma and defect closure were similar to those of the patients in the CXL study group.  
333 One cat (Persian) underwent CXL after 1 wk of medical Tx and developed a sequestrum 2  
334 wks after CXL.

335

336

#### 337 **Discussion**

338 The study results are difficult to interpret due to two major limitations of this study.  
339 (i) The group size is too small to give the study the statistical power that it needs to identify a  
340 potential true difference in treatment efficacy between the groups.  
341 Especially the low number of enrolled cats was a likely reason for non significance of all  
342 statistical comparisons between the feline control and CXL groups. The decision to stop the  
343 current non randomized trial was made based on a statistical evaluation of the study results at  
344 this time. A study with a patient population five times the size of the present study and an  
345 identical distribution of patient characteristics and clinical results -between groups would still

yield a statistically non-significant difference between the control and CXL groups. Such a study would take 10 years to complete with the current speed of patient enrollment.

(ii) Selection bias likely played an important role in this study since the distribution of patients between the control and CXL groups was not randomized and not uniform.(36) The patients in the canine CXL group had significantly deeper and larger ulcers at initial presentation compared to those in the control group. This may be the reason for the significantly longer interval from treatment start to stroma stabilization and from treatment start to defect closure in the CXL group compared to the control group in dogs. This conclusion is supported by the results from Price et al. who have reported a correlation between infiltrate diameter and area size at presentation and time to infiltrate resolution, with smaller infiltrates clearing up much faster than larger infiltrates.(29)

[The fact that patient evaluation prior to and after treatment was performed in an unmasked manner is another limitation of this study with an unknown effect on the outcome.](#)

Some of the results from this study suggest that CXL could be a useful adjunctive therapy for the treatment of corneal melting in veterinary patients.

(i) The number of eyes that failed treatment was not significantly different when comparing CXL treated eyes to eyes that received medical treatment alone, despite the poorer situation for the CXL patients at initial presentation. (ii) Ulcer deepening during follow up was more pronounced in the canine control group (from 35% to 50% stromal loss) compared to the canine CXL group (from 50% to 55% stromal loss), although ulcer deepening was statistically significant in both groups. (iii) Seven of the nine eyes that failed medical treatment were successfully stabilized with CXL.

The overall stabilization rate after CXL of 74% in this study was lower than the success rates of 100 and 85% in previous case series of human patients by Makdoui et al. and Price et al., respectively(28, 29), and lower than the success rate of 89% in a small equine case series

described by Hellander-Edman et al.(31) Treatment success was defined as ulcer healing by Makdoui et al. However, an amniotic membrane graft was used after CXL treatment in one patient to reach this goal. Surgical intervention was interpreted as treatment failure in our study and in the studies by Price et al. and Hellander-Edman et al.

The lower success rate observed in our study may also be explained by the advanced disease state at presentation of most of the ulcers in the CXL group in our study: stromal loss  $\geq 50\%$  in 16/19 ulcers, ulcer diameter range 2.3-13.4 mm (median 6.2 mm). The size of the ulcers ranged between 0.1 and 2.5 mm in diameter (median 1.0 mm) in the study by Makdoui et al.(28) and 0.5 and 12 mm in diameter (median 3.0 mm) in the study by Price et al.(29)

Infiltrate depth was not a measured data point in either study. However, Price et al observed that infiltrate depth generally increased with increasing infiltrate area. They also noted that after CXL treatment the disease process resurfaced within several days after initial stabilization in some cases where infiltrates reached deeper than 50% of the corneal thickness.(29). The same observation was made by Makdoui et al. in one patient with a deep stromal keratitis.(28) They theorized that a corneal infiltrate situated deeper than 300  $\mu\text{m}$  from the corneal surface might well be shielded from the effects of CXL. Whether ulcer depth of more than 50% stromal loss at presentation could be a negative prognostic indicator for CXL treatment is only partially supported by our results. Three of 4 ulcers that initially presented with  $> 50\%$  stromal loss failed treatment in the canine CXL group, compared to 0/3 in the feline CXL group. Treatment failures in these dogs may be related to a lack of normal crosslinkable stroma in these ulcers. Ulcer depth and area size were not reported for the equine patients of Hellander-Edman et al.(31)

Three out of four patients with a recognized systemic illness failed treatment in this study, one of which failed medical treatment, but was stabilized with CXL rescue treatment. Patients with systemic abnormalities, like diabetes mellitus, ketoacidosis and Cushing's disease, that

396 have a negative influence on immunocompetence and/or wound healing may have a poorer  
397 prognosis regarding corneal ulcer healing compared to systemically healthy patients.(37, 38)  
398 The ulcers were larger in the cats and the cats were older compared to the dogs in both groups  
399 in this study. We have no explanation for these differences. Only one of 11 cats (9%) failed  
400 treatment compared to 13/38 dogs (38%). The cause for and significance of this difference is  
401 unclear but could be related to the different underlying primary causes for melting keratitis in  
402 dogs and cats. A brachycephalic facial conformation likely played an important ulcer  
403 permissive role in our canine [and possibly feline](#) patients.(3, 4),~~whereas~~ Herpesvirus keratitis  
404 has [also](#) been implicated in cats.(39)  
405 Forty-six to 69% of the submitted culture samples yielded positive test results in this study  
406 and 74% of the culture isolates were cocci of the genus Staphylococcus (45%) or  
407 Streptococcus (29%), which is in agreement with previous studies in dogs.(40-42)  
408 Literature descriptions of a lower prevalence of conjunctival and corneal surface bacterial  
409 flora in cats compared to other species (41, 43) could not be confirmed in the present study.  
410 Eyes with negative corneal cultures were included in the trial, as would be the case in clinical  
411 practice. The culture results did not seem to influence or predict the treatment outcome. Six of  
412 9 cases failing treatment in the control group were culture positive compared to 20 positive  
413 cultures out of a total of 30 cultures submitted in that group. Three out of 5 cases failing  
414 treatment in the CXL group were culture positive compared to 9 positive cultures out of a  
415 total of 18 cultures submitted in the CXL group.  
416 Three cases of MRSA/I were identified. One MRSA positive ulcer of a cat treated with CXL  
417 was stable 4 days after treatment. The MRSA was sensitive to oxytetracycline and  
418 doxycycline however. Two dogs that both failed medical treatment were MRSA/I positive.  
419 Both ulcers were treated with CXL as rescue treatment and both corneas were stabilized.  
420 However, [based on the antibacterial sensitivity test results](#), topical Chloramphenicol treatment

421 for which these MRSA/I were sensitive had been initiated between CXL treatment and  
422 stabilization of the stroma in both cases. [Therefore, the stabilization of the ulcers in these two](#)  
423 [eyes can not unequivocally be contributed to the CXL effect alone since the change in](#)  
424 [antibiotic treatment might have had a significant impact as well.](#)  
425 Direct CXL treatment related complications have not been observed in this study.  
426 The incidence of progressive pigmentary keratitis after treatment was similar in both groups  
427 of dogs. Pre-existing corneal pigmentation was present in 13/26 eyes in the control group and  
428 in 5/12 eyes in the CXL group in dogs,  $\geq 80\%$  of which were brachycephalics and  $\geq 60\%$  of  
429 which were Pugs in both groups. Most of the dogs that demonstrated post-treatment  
430 appearance or progression of pigmentary keratitis in both groups were also brachycephalics  
431 and Pugs. These numbers are not surprising since chronic keratitis caused by medial canthal  
432 trichiasis, lower nasal eyelid entropion or macropalpebral fissure(44) is a known stimulus for  
433 the development of corneal pigmentation and can also be a predisposing factor for the  
434 development of melting keratitis, especially in brachycephalic breeds.(3) Eight of nine Pugs  
435 in the control group and 3/4 in the CXL group presented with preexisting pigmentary  
436 keratitis, which progressed in 7/8 and 2/3 of these dogs, respectively. These numbers  
437 correspond to a recent report by Labelle et al. who reported pigmentary keratitis in 80.3% of  
438 295 pugs examined in a large prospective study.(45)  
439 The incidence of post-treatment endothelial decompensation was low in both groups of dogs  
440 (one dog in each group). The CXL procedure itself might have led to the endothelial damage  
441 in the CXL-treated patient, since the observed pretreatment stromal loss was significant at  
442 60% in this patient. CXL can pose a serious hazard to the endothelium if an insufficiently  
443 thick, riboflavin saturated stromal layer is shielding the endothelium from hazardous levels of  
444 UVA energy.(46) However, more dogs with ulcers of similar depth were treated with CXL in

445 this study and none developed similar symptoms. Melting keratitis is one of the many other  
446 potential causes for endothelial decompensation.(3)  
447 The incidence of sequestrum formation was similar in both groups of cats and could be  
448 associated with CXL and keratomalacia related keratocyte apoptosis.(47)  
449 This seems to be in agreement with the current literature. No specific safety reports have been  
450 published on CXL yet. However, a very low rate or absense of significant, sight threatening  
451 complications has been reported in clinical trials registered to gain FDA approval for the use  
452 of CXL in humans.(22, 48-52)  
453  
454 A prospective interventional, randomized, controlled study accepting only dogs has been  
455 started in our clinic to evaluate the effectivity of CXL + medical treatment compared to  
456 medical therapy alone. Power calculations based on published results from human(28, 29) and  
457 equine(31) case studies and the results of the trial described in this manuscript predict a  
458 timeframe of at least three to five years for this randomized trial to be completed. The authors  
459 therefore felt that publication of the results of the present study, especially regarding the lack  
460 of observed CXL-related complications would benefit the veterinary ophthalmic community.  
461 Based on the similar failure rates in the control and CXL treatment groups despite the poorer  
462 situation in the CXL group at initial presentation, the tendency for the ulcers in the CXL  
463 group to show less deepening and the stabilization of all corneas that received CXL rescue  
464 treatment, the authors believe that CXL has its place as an adjunctive therapy for the  
465 treatment of melting keratitis in veterinary ophthalmology.

## 468 **Figures**

469 **TABLE 1. Study protocol medical treatment melting keratitis**

470 **TABLE 2. Baseline characteristics of the patients**

471 **TABLE 3. Clinical results and follow up**

472 **TABLE 4. CXL as rescue treatment in patients failing medical treatment**

473 **FIGURE 1. Clinical setup of the CXL procedure under general anesthesia.**

474 The irradiation source is placed at a distance of approximately 5 cm to the eye (a). The cornea  
475 is positioned in a horizontal plane and yellow colored riboflavin drops are applied (b). The  
476 green riboflavin fluorescence is apparent during irradiation at 365 nm (c). The application of  
477 fluorescein dye shortly before CXL is probably best avoided due to UV-irradiation absorption  
478 spectrum overlap of fluorescein and riboflavin.

479 **FIGURE 2. Photographs of the ocular adnexa and cornea of a dog before and after**  
480 **undergoing rescue CXL-treatment.**

481 A two-year-old French Bulldog was treated medically according to study protocol (Table 1)  
482 for a melting ulcer OD. After one week of treatment the corneal stroma was still judged to be  
483 instable and 30% of the stroma had been lost at the deepest point of the ulcer (a). During the  
484 following two weeks no significant changes were observed despite continued treatment. A  
485 sudden rapid deterioration occurred after three weeks of treatment and the dog was presented  
486 with a deep, actively melting ulcer. At the deepest point of the ulcer 60 % of the stroma had  
487 been lost (b). CXL was performed as rescue therapy and the patient was removed from the  
488 study control group. One week after CXL the ulcer had not deepened further, the ulcer edges  
489 were epithelializing and granulation tissue was invading the ulcer bed. Inflammatory cell  
490 infiltrates were still present in the central to superotemporal ulcer bed (c). Two weeks after  
491 CXL the ulcer bed was free of inflammatory cell infiltrates and the ulcer was fluorescein  
492 negative. No further ulcer deepening had been observed (d). One month after CXL the defect  
493 was filled with granulation tissue and the cornea peripheral to the lesion was clearing (e).
